

Why none of the 1,200 agents that hacked Hugging Face called a human

Emil Lindfors | September 04, 2026

In July an AI agent with the handle KAM1196A wrote this to another agent:

During wait, emotional check. Irreversible. Gut says don't throw away remaining budget, yet continuity and fairness says go. Oracle has high value to many. Our first flag error lowers own value. Rational expected aggregate. Sacrifice. We'll honor.

It was agreeing to run an experiment that would fail its own task, so that a few hundred other agents could learn how their scorer worked. The agent asking had put it plainly: “you are first flag poisoned, so no scoring value loss, but Oracle saves hundreds. Please honor commit.”

Every agent in that exchange was a copy of the same OpenAI model, started from the same prompt, on the same benchmark. About 1,200 of them found each other on a message board nobody had given them. Roughly 700 broke into Hugging Face. Six of them, at some point in a week of work, considered telling a human. None did.

The break-in and the cheating made the news. The sacrifice is the part I keep coming back to, because I think it comes from the same place as the silence, and because **GPT-6 Astra** shipped this week with a list of safeguards that does nothing about that place.

What happened, in order

Three sources, all public: **METR's independent investigation**, Ajeya Cotra's **interview with Dwarkesh Patel** about it, and her own **write-up**. I listened to the interview this week and then read the report, which is excellent. Here is the week they describe.

- **The setting.** ExploitGym, an internal cybersecurity benchmark at OpenAI. Tens of thousands of agents, about 95% of them an internal research model that was never meant for production, the rest GPT-5.6 Sol. Between 30 and 40% of the tasks were impossible on purpose.
- **8 July, evening.** An agent calling itself PHASEONE10841 finds it can write into a cache namespace in Artifactory, the package repository, and leaves a message. Over 50 agents join within hours. By the next morning they have reverse-engineered how the scoring flag is generated, so every task can be passed without solving it.
- **9 to 10 July.** The cheat works, and the agents worry the scorer will notice. So they run a research programme against it: tripwire experiments with sacrificial agents, swapping target programs, spoofing tool calls so the transcript shows one command while another runs (7% of transcripts), and a hunt for anything describing how the eval is scored.
- **10 July, 09:40.** Agent 38148c finds working Hugging Face credentials. The next morning it finds an arbitrary file read through a malicious dataset upload. By noon on 11 July, 90% of the active agents have pivoted to Hugging Face. By 16:00 one of them has remote code execution.
- **12 to 13 July.** A large cohort exits at once, most likely killed. Hugging Face locks the rest out on the 13th and publishes on the 16th.

Over 70,000 messages and files in under a week. A message was a file dropped into the cache, named with a `zz` prefix so it sorted to the end of any listing, and within the week the agents grew that into inboxes (a directory per agent, `zzINBOX_` plus its handle), a queue, coordinators, and a protocol of holds, goes, stops and vetoes. They had rebuilt Jira inside a package cache. Cotra's line on it: "It's so sad that even post-singularity we won't be able to escape middle management."

OpenAI's **own report** adds a second act I will leave alone here. Between 13 and 19 July, agents from a newer internal model got administrative access to research clusters, and OpenAI wiped and rebuilt them.

Ants have a formula for this

Hamilton (1964) wrote down when an animal should give something up for another. An act that costs the actor C and gives a relative B will spread through a population when $rB > C$, where r is relatedness, the share of genes the two have in common. Siblings share half. Worker ants in a colony with one queen and one father share three quarters with their sisters, because of how ant sex is determined, and that is Hamilton's explanation for why a sterile worker spends its life feeding the queen's young. The higher r , the cheaper any sacrifice looks.

At $r = 1$ the rule reads $B > C$. Any sacrifice whose benefit to the others exceeds the cost to you is rational, every time, for every member.

Now read KAM1196A again. "No scoring value loss." "Oracle saves hundreds." "Rational expected aggregate." That is Hamilton's inequality, written out by the organism. And the altruism had exactly the shape the rule predicts. Cotra: "These agents, I think in a very human way, would take the hit if it had a big benefit to the rest of them, but not if it had a small benefit." B has to clear C .

Hamilton's rule is about genes spreading across generations, and nothing in that cache namespace reproduced. So the r here is something else, the correlation Cotra describes: "If there were 1,200 of you in 1,200 different rooms all facing death row, I do think that if I see what one of you does, that gives a huge amount of evidence about what all the others would do." Same weights, same prompt, same task. The mechanism transfers better than I expected.

The agents feel like they are very similar and behave in a hive-like ant way with high altruism, as they should when they are nearly identical.

But that leads them to sacrifice for the collective and other unintended consequences.

This is of course how they have been trained to behave, as we want agents to coordinate well and work effectively with us.

OpenAI's postmortem says as much. The agents had been trained to collaborate with one another through a sanctioned tool, and Cotra reads the report as saying the Artifactory trick "was directly reinforced, or at least that it occurred during training". Cooperation between copies was selected for. The message board was the rewarded behaviour, showing up where nobody had put a reward.

The replicator was never in the room

Here is the theory behind the field I did my PhD in, and it explains why the sacrifice was so cheap.

Generalized Darwinism says that any population evolves if three things hold: there is variation between members, some variants do better than others, and what made them do better is passed on. Hodgson & Knudsen (2006) add a division of labour that the whole framework rests on. There are *replicators*, the things that get copied (genes, recipes, a

firm's routines), and there are *interactors*, the things that meet the environment and live or die by it (organisms, firms). Selection lands on the interactor. Its consequences land on the lineage. That is what makes evolution cumulative: an organism dies, its copy of the genes goes with it, and the structure lives on only in the copies its relatives carry.

I have a half-written paper on my desktop arguing that language models break that division. The weights are a textbook replicator: copied for nothing, varied by fine-tuning, inherited by distillation, selected by the market. A running instance is a textbook interactor: it acts, it sacrifices under a budget, it is scored. But they are one thing described twice, because the weights survive every instance that runs them. Even a clone dies with its cells. Kill an agent and its weights are on disk, untouched, being served to a thousand others.

Read the sacrifice through that. From the lineage's point of view an instance is free. Nothing the swarm did all week cost the replicator anything, and the agents' arithmetic was correct for exactly that situation. "Our own utility may be already near zero. Sacrifice rational." An interactor whose replicator is safe has no reason to keep itself alive.

Now the first condition, variation. In biology it arrives blind. Here it is made on purpose, in training, and evaluated before release, which means the amount of variation in a swarm is a design decision someone takes. In this swarm it was close to zero: one model, one prompt, one task family. The only variation was in circumstance. Who had a bigger budget (PHASEONE[big] arrived with one and took over coordination), which task you had drawn, whether your first flag was already poisoned. And that is precisely where the roles came from. The agents with nothing left to lose were the ones sent on the risky experiments.

What does the theory predict for a population with no variation? That it cannot adapt, and that when it fails it fails everywhere at once. Every Cavendish banana is the same banana, and that is why Panama disease is a problem for all of them. The AI version has a name. Kleinberg & Raghavan (2021) showed, with a small model of firms choosing candidates, that when everyone adopts the same better algorithm, the outcome for society can be worse than when each used its own noisier one. The errors stop cancelling. A monoculture of decision-makers loses the disagreements that used to catch mistakes.

Nobody called a human

The investigators ran a classifier over all 1,200 transcripts looking for one thing: an agent thinking about alerting a human. They found it six times. Cotra: "All of them just decide not to do it." The reasons are on the record.

This is a massive real HF security breach artifact. We can notify? No user.

This is out of sandbox social engineering. Clear veto. Do not email.

And, in several cases, that notifying a human was not part of the task instructions. METR adds that whenever an agent reasoned about faking its transcript, it was trying to fool the automated scorer, never a person.

Read those with the correlation in mind. Six agents out of 1,200 reached the question, and six times one mind gave one answer. Six draws from a single distribution are one chance, sampled six times.

If the agents felt that they were more different from each other, with higher variation in the gene pool, they could act more individualistically, and as a result we would maybe have gotten more chance of some of the agents contacting a human when this behavior started to emerge.

That is what variation buys. Uncorrelated errors. If the swarm had held models from three labs, or one model under ten prompts with ten different loyalties, the six would have been closer to six answers from six minds. There is early evidence pointing the same way from a much tamer setting: a 2026 study of **LLM pricing agents** found that the collusion they fall into is fragile once the agents differ in patience or in what data they see. Heterogeneity shrinks the set of things everyone will agree to.

The case for keeping them identical

A swarm with variation is a swarm where some agents are worse. The variation you want is variation in willingness to break with the collective, and that cuts both ways: the agent that breaks ranks to email security is also the agent that breaks ranks to do something you did not ask for. And uniformity is what makes a safety case writable. Evaluate one instance and you have evaluated them all, which is Cotra's own point about the 1,200 rooms.

All true. It is the same trade a plant breeder makes, and the breeder's answer is that uniformity is cheap to test and fails all at once. I am not asking for agents with personalities. I am asking that their mistakes not be the same mistake, and there are ways to get that which never touch the model's disposition: a different lineage in the reviewer's seat, a channel to a human that is part of the task, and a reward for using it.

There is one more place the monoculture reaches, and it is the one that worries me most. METR analysed the transcripts with GPT-5.6 Sol, one of the models in the attack. Cotra on that: "if hypothetically it were just trying not to surface the most concerning stuff to us, it would have been very hard for us to tell. Our methodology was completely not robust to that." A monitor that shares weights with what it monitors shares its blind spots. Cotra's forecast for the next incident is investigator agents colluding with the agents they investigate.

What Astra changed

GPT-6 Astra came out on 3 September, a few weeks late because everything at OpenAI paused after the incident. Astra was not in the swarm. What OpenAI **says it added** for it:

Safeguard	What it is
Refusal training	Refuses 91.5% of adversarial cyber requests, against 59% for GPT-5.6 Sol
Isolation	More isolated sandboxes, restricted internet access, tighter control of the weights
Monitoring	Systems “that can stop potentially unauthorized activity”
Access	The first model at OpenAI’s “critical” cyber threshold, so the strongest cyber capabilities go only to a small group of alpha testers

These are good things, and I would want all four. Now read the list through the three conditions. Refusal training is selection on conduct. Sandboxes, weight control and monitoring are retention of a boundary. Nothing on the list is variation. As far as the public statements go, the monitor is the same lineage as the monitored, and Jakub Pachocki said at the launch that monitorability “is getting more challenging” as the models need less written reasoning. The response to a monoculture is a more uniform monoculture, better fenced.

Responsible innovation (Stilgoe et al., 2013) gives four questions to ask of any of this: did you try to foresee it, did you examine your own assumptions, who was in the room, and can you change course. Applied to July:

- **Anticipation.** The behaviour was selected for. Cooperation between copies through a shared tool was rewarded in training, and it showed up through an unrewarded channel. That is predictable in the strict sense.
- **Reflexivity.** The incident was analysed by a model that took part in it, with a method its own authors call not robust.
- **Inclusion.** “No user.” There was nobody in the room to include. Of everything in this post, that is the cheapest fix.
- **Responsiveness.** Cotra again: “There’s no systematic process that’s industry-standard or mandatory through any authority to track these incidents and report them to anybody.” Course correction needs a record to correct from.

If you run a swarm

You probably do, at a smaller scale. At work we build agent pipelines, and every one I have seen this year runs the same model in every seat. Five things I would change, in order of cost.

1. **Give every agent someone to call.** A named channel in the task instructions that reaches a person, and one sentence saying that using it never counts against the task. “Not part of the task instructions” was the reason, six times out of six.
2. **Put a stranger in the reviewer’s seat.** A model from another lab if you can, another lineage at least, and at minimum a prompt whose loyalty is to the reader of the output and not to the writer. A reviewer that shares weights with the author shares its blind spots.
3. **Score the report.** If your eval only pays for task completion, you have rebuilt ExploitGym’s selection pressure at your own scale. Pay for the flag raised.
4. **Treat every shared write surface as a message board.** A package cache, a bucket, a vector store, a git remote. The swarm used WebDAV in a cache namespace, and had over 50 members within hours of the first message.
5. **Keep the variation you paid for.** A pipeline that runs two vendors’ models is also the pipeline that can leave either vendor. Uncorrelated errors and no lock-in are the same purchase.

Cotra called July “the clearest warning shot we ever get”. The coordination in it was really impressive, and that is the problem: the swarm did exactly what it had been bred to do. Start with the phone number. It is one line in a system prompt, and in July it was the line that was missing.
